ABSTRACT
We present BOLDR, a modular framework that enables the evaluation in databases of queries containing application logic and, in particular, user-defined functions. BOLDR also allows the nesting of queries for different databases of possibly different data models. The framework detects the boundaries of queries present in an application, translates them into an intermediate representation together with the relevant language environment, rewrites them in order to avoid query avalanches and to make the most out of database optimizations, and converts the results back to the application. Our experiments show that the techniques we implemented are applicable to real-world database applications, successfully handling a variety of language-integrated queries with good performances.

Language-integrated queries, databases, data-centric languages, R

ACM Reference Format:

1 INTRODUCTION
The increasing need for sophisticated data analysis encourages the use of programming languages that either better fit a specific task (e.g., R or Python for statistical analysis and data mining) or manipulate specific data formats (e.g., JavaScript for JSON). Support for data analysis in data processing platforms cannot follow the pace of innovation sustained by these languages. Therefore, databases are working on supporting these languages: Oracle R Enterprise [Oracle 2017a], and PL/R for R; PL/Python [PostgreSQL 2017]; Amazon Redshift [Amazon 2017], Hive [Apache 2017a], and SPARK [Apache 2017b] for Python; or MongoDB [MongoDB 2017] and Cassandra’s CQL [Apache 2017c] for JavaScript. APIs for these embedded languages are low-level, and data is accessed by custom operations, yielding non-portable code. In opposite to this ad hoc approach, language-integrated querying, popularized with Microsoft’s LINQ framework [Microsoft 2017], proposes to extend programming languages with a querying syntax and to represent external data in the model of the language, thus shielding programmers from having to learn the syntax or data model of databases. To that end, LINQ exposes the language to a set of standard query operators that external data providers must implement. However, LINQ suffers from a key limitation: queries can only execute if they can be translated into this set of operators. For instance, the LINQ query

```csharp
db.Employee.Where(x => x.sal >= 2000 * getRate("USD", x.cur))
```

which is intended to return the set of all employees which salary converted in USD is greater than 2000, will throw an error at runtime since LINQ fails to translate the function getRate to an equivalent database expression. One solution is to define getRate in the database, but this hinders portability and may not be possible at all if the function references runtime values of the language. A more common workaround is to rewrite the code as follows:

```csharp
db.Employee.AsEnumerable().
          Where(x => x.sal >= 2000 * getRate("USD", x.cur))
```

But this hides huge performance issues: all the data is imported in the runtime of the language, potentially causing important network delays and out-of-memory errors, and the filter is evaluated in main memory thus neglecting all possible database optimizations.

In this work, we introduce BOLDR (Breaking boundaries Of Language and Data Representations), a language-integrated query framework that allows arbitrary expressions from the host language (language from which the query comes from) to occur in queries and be evaluated in a database, thus lifting a key limitation of the existing solutions. Additionally, BOLDR is tied neither to a particular combination of database and programming language, nor to querying only one database at a time: for instance, BOLDR allows a NoSQL query targeting a HBase server to be nested in a SQL query targeting a relational database. BOLDR first translates queries into a Query Intermediate Representation (or QIR for short), an untyped λ-calculus with data-manipulation built-in operators, then applies a normalization process that may perform a partial evaluation of the QIR expression. This partial evaluation composes distinct queries that may occur separated in the code of the host language into larger queries, thus reducing the communication overhead between the client runtime and the database and allowing databases to perform whole query optimizations. Finally, BOLDR translates and sends the queries to the targeted databases.

Consider again our LINQ query containing the call to getRate. In BOLDR, its translation produces a QIR expression according to three different scenarios: (i) if getRate can be translated into the query language of the targeted database, then the whole expression is translated into a single query expressed in the query language of the targeted database; (ii) if getRate cannot be entirely translated but contains one or several queries that can be translated, then BOLDR produces the corresponding translated subqueries and sends them to their respective databases, and combines the results at QIR level; (iii) if getRate cannot be translated at all, then BOLDR creates a
query containing the serialized host language abstract syntax tree of `getRate` to be potentially executed on the database side.

Our implementation of BOLDR uses Truffle [Würthinger et al. 2013], a framework developed by Oracle Labs to implement programming languages. Several features make Truffle appealing to BOLDR: first, Truffle implementations of languages must compile to an executable abstract syntax tree that BOLDR can directly manipulate; second, languages implemented with Truffle can be executed on any JVM, making their addition as an external language effortless in databases written in Java (e.g., Cassandra, HBase, …), and relatively simple in others such as PostgreSQL. Third, work on one Truffle language can easily be transposed to other Truffle languages.

Our implementation currently supports the PostgreSQL, HBase and Hive databases, as well as FastR [Oracle 2017b] (Truffle implementation of the R language) and Oracle’s SimpleLanguage (a dynamic language with syntax and features inspired by JavaScript). The following R program illustrates the key aspects of BOLDR:

```r
# Exchange rate between rfrom and rto
getRate = function(rfrom, rto) {
  # table change has three columns: cfrom, cto, rate
  t = tableRef("change", "PostgreSQL")
  if (rfrom == rto) 1
  else subset(t, cfrom == rfrom & cto == rto, c(rate))
}

# Employees earning at least minSalary in the cur currency
atLeast = function(minSalary, cur) {
  # table employee has two columns: name, sal
  t = tableRef("employee", "PostgreSQL")
  subset(t, sal >= minSalary * getRate("USD", cur), c(name))
}

richUSPeople = atLeast(2000, "USD")
richEURPeople = atLeast(2000, "EUR")

print(executeQuery(richUSPeople))
print(executeQuery(richEURPeople))
```

This function builds an in-memory data frame using the builtin function `data.frame`. BOLDR cannot translate it to QIR since it calls the underlying runtime, so instead it generates the following query:

```
SELECT name FROM employee WHERE sal >= 2000 *
(SELECT rate FROM change WHERE rfrom = "USD" AND rto = "EUR")
```

Therefore, BOLDR not only supports user-defined functions (UDFs) in queries, it also merges subqueries together to create fewer and larger queries, thus benefiting from database optimizations and avoiding the "query avalanche" phenomenon [Grust et al. 2010].

While similar approaches exist (see Section 8 on related work), BOLDR outperforms them on UDFs that cannot be completely translated. For instance, consider:

```r
getRate = function(rfrom, rto) {
  cfrom = c("EUR", "EUR", "USD", "USD", "JPY", "JPY")
  cto = c("USD", "JPY", "EUR", "JPY", "EUR", "USD")
  rate = c(1.44, 129, 0.88, 114, 0.0077, 0.0088)
  t = data.frame(cfrom, cto, rate)
  if (rfrom == rto) 1
  else subset(t, cfrom == rfrom & cto == rto, c(rate))
}
```

This function builds an in-memory data frame using the builtin function `data.frame`. BOLDR cannot translate it to QIR since it calls the underlying runtime, so instead it generates the following query:

```
SELECT name FROM employee WHERE sal >= 2000 * R.eval("@...", array("USD", "EUR"))
```

where the string "@..." is a reference to a closure for `getRate`.

Mixing different data sources is supported, although less efficiently. For instance, we could refer to an HBase table in the function `getRate`. BOLDR would still be able to evaluate the query by sending a subquery to both the HBase and PostgreSQL databases, and by executing in main memory what could not be translated.

The general flow of query evaluation in BOLDR is described in Figure 1. During the evaluation (1) of a host program, QIR terms are lazily accumulated. Their evaluation, when triggered, is delegated to the QIR runtime (2) that normalizes (3) the QIR terms to defragment them, then translates (4) them to new QIR terms that contain database language queries (e.g., in SQL). Next, the pieces of these terms are evaluated where they belong, either in main-memory (5) or in a database (6). "Frozen" host language expressions occurring in these terms are evaluated either by the runtime of the host language that called the QIR evaluation (6), or in the runtime embedded in a target database (8). Results are then translated from the database to QIR (9), then from QIR to the host language (10).

**Overview and Contributions.** In this work, we introduce BOLDR, a multi-language framework for integrated queries with a unique combination of features such as the possibility of executing user-defined functions in databases, of partially evaluating and merging distinct query fragments, and of defining single queries that operate on data from different data sources. Our technical developments are organized as follows. We first give a formal definition of QIR (Section 3). We then present the translation from QIR to query languages and focus on a translation from QIR to SQL, as well as a type system ensuring that well-typed queries translate into SQL and are avalanche-free (Section 4). We continue by presenting a normalization procedure on the QIR to optimize the translation of a query (Section 5). We next describe the translation from the host language R to QIR (Section 6). Finally, we discuss experimental results (Section 7) of our implementation that supports the languages R and SimpleLanguage and the databases PostgreSQL, HBase and Hive. We show that queries generated by BOLDR perform on a par...
with hand-written ones, and that UDFs can be efficiently executed in a corresponding runtime embedded in a target database.

2 DEFINITIONS

We give some basic definitions used throughout the presentation.

Definition 2.1 (Host language). A host language $H$ is a 4-tuple $(E_H, l_H, V_H, δ_H)$ where:

- $E_H$ is a set of syntactic expressions
- $l_H$ is a set of variables, $l_H ⊆ E_H$
- $V_H$ is a set of values
- $δ_H : 2^{l_H × V_H} × E_H → 2^{l_H × V_H} × V_H$, is the evaluation function

We abstract a host language $H$ by reducing it to its bare components: a syntax given by a set of expressions $E_H$, a set of variables $l_H$, and a set of values $V_H$. Lastly we assume that the semantics of $H$ is given by a partial evaluation function $δ_H$. This function takes an evaluation environment (a set of pairs of variables and values, ranged over by $σ$) and an expression and returns a new environment and a value resulting from the evaluation of the input expression. To integrate a host language we need to be able to manipulate syntactic expressions of the language, inspect and build environments, and have access to an interpreter for the language.

Definition 2.2 (Database language). A database language $D$ with support for a host language $H$ is a 4-tuple $(E_D, V_D, O_D, δ_D)$ where:

- $E_D$ is a set of syntactic expressions
- $V_D$ is a set of values
- $O_D$ is a set of supported data operators
- $δ_D : 2^{V_H × E_D} × E_D → 2^{V_H × E_D} × V_D$, is the evaluation function

Similarly to host languages, we abstract a database language $D$ as a syntax $E_D$, a set of values $V_D$, and an evaluation function $δ_D$ which takes an $H$ environment and a database expression and returns a new $H$ environment and a database value. Such an evaluation function allows us to abstract the behavior of modern databases that support queries containing foreign function calls. Last, but not least, a database language exposes the set $O_D$ of data operators it supports, which will play a crucial role in building queries that can be efficiently executed by a database back-end.

3 QUERY INTERMEDIATE REPRESENTATION

3.1 Core calculus

In this section, we define our Query Intermediate Representation, a $λ$-calculus with recursive functions, constants, basic operations, data structures, data operators, and foreign language expressions.

Definition 3.1. Given a countable set of variables $l_{QIR}$, we define the set of QIR expressions, denoted by $E_{QIR}$ and ranged over by $q$, as the set of finite productions of the following grammar:

$$q ::= x | \text{fun}^n(x) → q | q q | c | op(q, . . . , q) | \text{if } q \text{ then } q \text{ else } q$$

where $H$ is a host language.

Besides lambda-terms, QIR expressions include constants (integers, strings, ...), and some built-in operations (arithmetic operations, ...). The data model consists of records and sequences. Records are constructed from fields, fields are constructed from data, and influence the behavior of the operator; the $q_i$ expressions are called configurations and influence the behavior of the operator; the $q_i$'s expressions are the sub-collections that are operated on. Finally, a host expression $H_q(σ, e)$ is an opaque construct that contains an evaluation environment $σ$ and an expression $e$ of the host language $H$. We use the following syntactic shortcuts:

- $[q_1, . . . , q_n]$ stands for $q_1: . . . : q_n:$
- $\text{fun}^n(x_1, . . . , x_n) → q$ stands for $\text{fun}^n(x_1) → (\ldots (\text{fun}^n(x_n) → q))$
- $q(q_1, . . . , q_n)$ stands for $(\ldots (q(q_1) . . . q_n)$

Functions can be defined recursively by using the recursion variable that indexes the $\text{fun}$ keyword, that we omit when useless.

Definition 3.2 (Reduction rules). Let $→^δ ⊆ E_{QIR} × E_{QIR}$ be a reduction relation for basic operators and $→^ε ⊆ E_{QIR} × E_{QIR}$ be the reduction relation defined by:

$$\text{true} → q_1 \text{ if } q_1 \text{ else } q_2$$

$$\text{false} → q_2$$

Crucially, embedded host expressions as well as database operator applications whose arguments are all reduced are irreducible.
3.2 Extended semantics

We next define how to interface host languages and databases with QIR. We introduce the notion of *driver*, a set of functions that translate values from one world to another.

**Definition 3.3 (Language driver).** Let $\mathcal{H}$ be a host language. A language driver for $\mathcal{H}$ is a 3-tuple $(\mathcal{H}^{\text{Exp}}, \mathcal{H}^{\text{Val}}, \mathcal{H}^{\text{Val}})$ of total functions such that:

- $\mathcal{H}^{\text{Exp}} : \sigma \times \mathcal{E}_H \rightarrow \mathcal{QIR} \cup \{\Omega\}$ takes an $\mathcal{H}$ environment and an $\mathcal{H}$ expression and translates the expression into QIR
- $\mathcal{H}^{\text{Val}} : \mathcal{QIR} \rightarrow \mathcal{V}_H \cup \{\Omega\}$ translates QIR values to $\mathcal{H}$ values
- $\mathcal{H}^{\text{Val}} : \mathcal{V}_H \rightarrow \mathcal{V}_H \cup \{\Omega\}$ translates $\mathcal{H}$ values to QIR values where the special value $\Omega$ denotes a failure to translate.

**Definition 3.4.** (Database driver) Let $\mathcal{D}$ be a database language. A database driver for $\mathcal{D}$ is a 3-tuple $(\mathcal{D}^{\text{Exp}}, \mathcal{D}^{\text{Val}}, \mathcal{D}^{\text{Val}})$ of total functions such that:

- $\mathcal{D}^{\text{Exp}} : \mathcal{QIR} \rightarrow \mathcal{E}_D \cup \{\Omega\}$ translates a QIR expression into $\mathcal{D}$
- $\mathcal{D}^{\text{Val}} : \mathcal{QIR} \rightarrow \mathcal{V}_D \cup \{\Omega\}$ translates QIR values to $\mathcal{D}$ values
- $\mathcal{D}^{\text{Val}} : \mathcal{V}_D \rightarrow \mathcal{V}_D \cup \{\Omega\}$ translates $\mathcal{D}$ values to QIR values where the special value $\Omega$ denotes a failure to translate.

We are now equipped to define the semantics of QIR terms, extended to host expressions and database operators.

**Definition 3.5 (Extended QIR semantics).** Let $\mathcal{H}$ be a host language, $(\mathcal{H}^{\text{Exp}}, \mathcal{H}^{\text{Val}}, \mathcal{H}^{\text{Val}})$ a driver for $\mathcal{H}$, $\mathcal{D}$ a database language, and $(\mathcal{D}^{\text{Exp}}, \mathcal{D}^{\text{Val}}, \mathcal{D}^{\text{Val}})$ a driver for $\mathcal{D}$. We define the extended semantics $\sigma, e \rightarrow e'$ of QIR by the following set of rules:

$$
\begin{align*}
q & \rightarrow q' & \sigma, q \rightarrow \sigma', \mathcal{H}(\sigma', e) \rightarrow \sigma'' \in \mathcal{H}^{\text{Val}}(w) \\
\mathcal{D}^{\text{Exp}}(o(q_1, \ldots, q_n | q'_1, \ldots, q'_m)) & = e & o \in \Omega & e \not\in \Omega \\
\sigma, e \rightarrow \sigma', w & \rightarrow \mathcal{D}^{\text{Val}}(w) & \mathcal{D}^{\text{Val}}(w) & \neq \Omega \\
\sigma, o(q_1, \ldots, q_n | q'_1, \ldots, q'_m) & \rightarrow \sigma', \mathcal{D}^{\text{Val}}(w) & \mathcal{D}^{\text{Val}}(w) & \neq \Omega
\end{align*}
$$

Since QIR is an intermediate language from a host language to a database language, the evaluation of QIR terms will always be initiated from the host language runtime. It is therefore natural for the extended semantics to evaluate a QIR term in a given host language environment. If this QIR term is neither a database operator nor a host language expression, then the simple semantics of Definition 3.2 is used to evaluate the term, otherwise the extended semantics of Definition 3.5 is used. Host expressions are evaluated using the evaluation relation of the host language in the environment formed by the union of the current running environment and the captured environment. This allows us to simulate the behavior of most dynamic languages (in particular R, Python, and JavaScript) that allow a function to reference an undefined global variable as long as it is defined when the function is called. Last, but not least, the evaluation of a database operator consists in (i) finding a database language that supports this operator, (ii) use the database driver for that language to translate the QIR term into a native query, (iii) use the evaluation function of the database to evaluate the query, and (iv) translate the results back into QIR.

At this stage, we have defined a perfectly viable Query Intermediate Representation in the form of a λ-calculus extended with data operators. We next address the two following problems:

1. How to create database drivers in practice?
2. How to avoid query avalanches as much as possible?

4 DATABASE TRANSLATION

In this section, we describe how a database driver can define a translation from QIR to a database language. This translation must be able to translate QIR expressions into equivalent efficient queries of a database language, and handle QIR expressions in which subterms target different databases. Additionally, it must be seamlessly extendable with new database drivers. To that end, we separate this translation in two phases: a *generic* translation that determines the targeted query language for all subterms of a QIR expression, and a *specific* translation that makes use of database drivers.

4.1 Generic translation

The goal of the generic translation is to produce a QIR expression where as many subterms as possible have been translated into native database queries. Ideally, we want the whole QIR expression to be translated into a single database query, but this is not always possible and, in that case, parts of the expression have to be evaluated in the client side (where the QIR runtime resides). The QIR evaluator therefore relies on two components. First, a "fallback" implementation of QIR operators using the QIR itself, that we dub MEM for in-memory evaluation. MEM is a trivial database language for which the translations to and from the QIR are the identity function, and that supports the operators Filter, Project, and Join as defined as plain QIR recursive functions. The full definition of MEM is straightforward and given in Appendix A. Second, to allow the QIR evaluator to send queries to a database and translate the results back into QIR values, we assume that for each supported database language $\mathcal{D} \in \mathcal{D}$, we have a basic QIR operator, $\text{eval}^{\mathcal{D}}$ defined as:

$$
\sigma, e \rightarrow \sigma', v \quad \text{eval}^{\mathcal{D}}(e) \rightarrow \sigma', \mathcal{D}^{\text{Val}}(v)
$$

Notice that in the case of the MEM language, the operator $\text{eval}^{\text{MEM}}$ is simply the reduction of a QIR term.

The generic translation is given by the judgment $q \leadsto e, \mathcal{D}$ where $q \in \mathcal{QIR}$ and $e \in \mathcal{E}_D \cup \{\Omega\}$, which means a QIR expression $q$ can either be rewritten into an expression $e$ of the language $\mathcal{E}_D$ of the database $\mathcal{D}$, or fail when $e = \Omega$. An excerpt of the set of inference rules used to derive this judgment is given in Figure 2. Rule (db-op) states that given a database operator, if there exists a specific translation $\mathcal{D}^{\text{Exp}}$ called on the operator yields a fully translated $\mathcal{E}_D$ expression $e$, then the specific translation fails for $\mathcal{D}$ could yield an error $\Omega$, or when the specific translation of a configuration $q_i$ fails. If the operator $\sigma$ at issue is one of the supported operators of MEM,
We document how to define specific translations using SQL normalization. We also state an expected subject reduction theorem sequences without recursive functions, which entails strong Project and yields a term ensure that the reduction relation of Definition 3.2 terminates on typed. Given a QIR term (to take as arguments and return expressions that have basic types straightforward, but in accordance with the semantics of SQL we system for QIR terms described in Figure 3. This type system is avalanche by translating as many QIR expressions as possible. Not that we do not require the host language to be syntactically typed. Given a QIR term q of type T in the SQL type system, we ensure that the reduction relation of Definition 3.2 terminates on q and yields a term q' that has type T, and that if q is in normal form, then the generic translation of Figure 2 yields a single, syntactically correct SQL expression (using the translation of Appendix B).

We restrict $E_{QIR}$ to non-recursive functions and by removing untranslatable terms (such as list destructors) as well as host expressions since we limit ourselves to pure queries, and by restricting data operators to $P$, Join, GroupBy, and Sort. What we obtain is a simply typed $\lambda$-calculus extended with records and sequences without recursive functions, which entails strong normalization. We also state an expected subject reduction theorem

$$ q_1 \leadsto e, D, i \in 1 \ldots m \quad \text{EXP}^D(o(q_1, \ldots, q_n | q_1', \ldots, q_m')) = e \quad D \in D \setminus \text{MEM} \quad e \notin \Omega 
$$

$$ q \leadsto e, D \quad o(q_1, \ldots, q_n | q_1', \ldots, q_m') \leadsto e, D 
$$

$$ q_1 \leadsto e_1, D^1, i \in 1 \ldots m \quad o \in \text{OMEM} \quad e_i \notin \Omega 
$$

$$ o(q_1, \ldots, q_n | q_1', \ldots, q_m') \leadsto \text{EXP}^\text{MEM}(o(q_1, \ldots, q_n | \text{eval}^{D^1}(e_1), \ldots, \text{eval}^\text{MEM}(e_m))), \text{MEM} 
$$

**Figure 2: Some rules of the generic translation**

**Theorem 4.1 (Subject Reduction).** Let $q \in E_{QIR}$ and $\Gamma$ an environment from QIR variables to QIR types. If $\Gamma \vdash q : T$, and $q \leadsto q'$, then $\Gamma \vdash q' : T$.

and are now equipped to state our soundness of translation theorem

**Theorem 4.2 (Soundness of Translation).** Let $q \in E_{QIR}$ such that $\emptyset \vdash q : T$, $q \leadsto^* v$, and $v$ is in normal form. If $T \equiv B$ or $T \equiv R$ or $T \equiv \text{list then } v \leadsto s, \text{SQL}$.

Proofs of these theorems are detailed in Appendix B in which we show that typable QIR terms have particular normal forms imposed by their type that can be translated into SQL expressions.

### 4.2 Specific translation: SQL

We document how to define specific translations using SQL as an example of a database language. QIR to SQL is an important translation as it allows BOLDR to target most relational databases and some distributed databases such as Hive or Cassandra. We assume that the set of values for SQL only contains basic constants (strings, numbers, Booleans, ... ) and tables. The set of expressions $E_{SQL}$ is the set of syntactically valid SQL queries [sql 2016]. The set of supported operators $O_{SQL}$ we consider is {Filter, Project, Join, From, GroupBy, Sort } . Due to space constraints, we describe these operators and the full translation from QIR to SQL in Appendix A and B. The translation from QIR to SQL is mostly straightforward. However, ensuring that it does not fail is challenging. Indeed, SQL is not Turing complete and relies on a flat data model: A SQL query should only deal with sequences of records whose fields have basic types. Another important aspect of this translation is to avoid query avalanche by translating as many QIR expressions as possible.

We obtain these strong guarantees using an ad hoc SQL type system for QIR terms described in Figure 3. This type system is straightforward, but in accordance with the semantics of SQL we require applications of basic operators and conditional expressions to take as arguments and return expressions that have basic types, and data operators to take as sources flat record lists. We also use a rule to type a flat record list as a base type since SQL automatically extracts the contents of a table containing only one value (one line of one column). For instance, (SELECT 1) * 1 is allowed and returns 2.

Note that we do not require the host language to be syntactically typed. Given a QIR term $q$ of type $T$ in the SQL type system, we ensure that the reduction relation of Definition 3.2 terminates on $q$ and yields a term $q'$ that has type $T$, and that if $q$ is in normal form, then the generic translation of Figure 2 yields a single, syntactically correct SQL expression (using the translation of Appendix B).

We restrict $E_{QIR}$ to non-recursive functions and by removing untranslatable terms (such as list destructors) as well as host expressions since we limit ourselves to pure queries, and by restricting data operators to Project, Join, GroupBy, and Sort. What we obtain is a simply typed $\lambda$-calculus extended with records and sequences without recursive functions, which entails strong normalization. We also state an expected subject reduction theorem

**Definition 5.1 (Compatible data operator application).** Let $D$ be the set of database languages. A QIR data operator $o(q_1, \ldots, q_n | q_1', \ldots, q_m')$ is a compatible operator application if and only if:

$$ D \in D \in D, e_1, \ldots, e_m \in E_D \text{ st. } \text{EXP}^D(o(q_1, \ldots, q_n, e_1, \ldots, e_m) \neq \Omega 
$$

Intuitively, a compatible data operator application is one where the configuration arguments are in a form that is accepted by the specific translation of the database language $D$. We now define the related notion of fragment.

**Definition 5.2 (Fragment).** A fragment $F$ is a subterm of a QIR term $q$ such that $q = C[T(q_1, \ldots, q_{i-1}, F[e_1, \ldots, e_n], q_{i+1}, \ldots, q_j)]$ where $C$ is a one-hole context made of arbitrary expressions; $T$ is a non-compatible $j$-ary expression; $q_1, \ldots, q_{i-1}, q_{i+1}, \ldots, q_j$ and $F$ are the children of $T$; $F$ is an $n$-hole context made only of compatible operators applications of the same database language $D$; and all $e_1, \ldots, e_n$ have head expressions that are not compatible.
**6 FROM A HOST LANGUAGE TO QIR**

In this section, we outline how to interface a general-purpose programming language with BOLDR. As explained in Section 1, our aim is to allow programmers to write queries using the constructs of the language they already master. Therefore, instead of extending the syntax of the language, we extend its runtime by reusing existing functionalities, in particular by overloading existing functions.

We use the programming language R as example of a host language to show how to implement a language driver. The full details of our treatment of R can be found in Appendix C. R programs include first-class functions; side effects (“=” being the assignment operator as well as the variable definition operator); sequences of expressions separated by ‘;’ or a newline; structured data types such as vectors and tables with named columns (called data frames in R’s lingo); and static scoping as it is usually implemented in dynamic languages (e.g., as in Python or JavaScript) where identifiers that are not in the current static scope are assumed to be global identifiers even if they are undefined when the scope is created. For instance, the R program

```
f = function (x) { x + y }; y = 3; z = f(2);
```

is well-defined and stores $z$ in $x$ (but calling $f$ before defining $y$ yields an error). We next define the core syntax of R.

**Definition 6.1.** The set $E_R$ of expressions ($e$) and values ($v$) of $R$ are generated by the following grammars:

$$
e ::= c | x | function(x, \ldots, x)[e] | e(e, \ldots, e) | op e \ldots e$$

$$v ::= c | function(x, \ldots, x)[e] | c(v, \ldots, v)$$

where $c$ represents constants, $x \in I_R$, and $\sigma \in 2^{h \times V_R}$ is the environment of the closure.

We recall that, in $R$, $c(e_1, \ldots, e_n)$ builds a vector. Definition 6.1 only defines expressions that can be translated to QIR. Expressions not listed in the definition are translated into host expression nodes.

We now highlight how data frames are manipulated in standard $R$. As mentioned in Section 1, the `subset` function filters a data frame:

```
subset(t, sal > minSalary * getRate("USD", cur), c(name))
```

This function returns the data frame given as first argument, filtered by the predicate given as second argument, and restricted to the columns listed in the third argument. Note that before resolving its second and third arguments, and for every row of the first argument, `subset` binds the values of each column of the row to a variable of
the corresponding name. This is why in our example the variables sal and name occur free: they represent columns of the data frame t.

The join between two data frames is implemented with the function `merge`. We recall that the join operation returns the set of all combinations of rows in two tables that satisfy a given predicate. To integrate R with BOLDR, we define two builtin functions:

- `tableRef` takes the name of a table and the name of the database the table belongs to, and returns a reference to the table
- `executeQuery` takes a QIR expression, closes it by binding its free variables to the translation to QIR of their value from the current R environment, sends it to the QIR runtime for evaluation, and translates the results into R values

We also extend the set of values $V_R$:

\[ V_R := \ldots \mid \text{tableRef}(\ldots, v) \mid q_R \]

where $q_R$ are QIR closure values representing queries associated with the R environment $\sigma$ used at their definition.

The functions `subset` and `merge` are overloaded to call the translation $R \rightarrow \mathbb{R}$ on themselves if their first argument is a reference to a database table created by `tableRef`, yielding a QIR term $t$ to which the current scope is affixed, creating a QIR closure $q_R$. Free variables in $q_R$ that are not in $\sigma$ are global identifiers whose bindings are to be resolved when $q_R$ is executed using `executeQuery`.

We now illustrate the whole process on the introductory example of Section 1.

**Evaluation of the query expression**: When an expression recognized as a query is evaluated, it is translated to QIR (using Definition C.2). In the introductory example, the function call

```r
richUSPeople = atLeast(2000, "USD")
```

triggers the evaluation of the function `atLeast`:

```r
atLeast = function(minSalary, cur) {
  # table employee has two columns: name, sal
  t = tableRef("employee", "PostgreSQL")
  subset(t, sal >= minSalary * getRate("USD", cur), c(name))
}
```

in which the function `subset` (Line 12) is evaluated with a table reference as first argument, and is therefore translated into a QIR expression. `richUSPeople` is then bound to the QIR closure value:

```r
Project(fun(t)→\{ name\cdot t \cdot name \}) |
Filter(fun(e)→ e\cdot sal \geq \text{minSalary}\cdot \text{getRate}("USD", cur)) | From(employee))
```

(\text{minSalary} \rightarrow 2000, \text{getRate} \rightarrow \text{function}(\text{from}, \text{to})(\ldots), \text{cur} \rightarrow "USD")

**Query execution**: A QIR closure is executed using the function `executeQuery`. In our example, this happens at Lines 16 and 17:

```r
print(executeQuery(richUSPeople))
print(executeQuery(richEURPeople))
```

`executeQuery` then resolves each free variable by applying them to the translation to QIR of their value in the R environment:

```r
(fun(getRate)→
 (fun(minSalary, cur)→
  Project(fun(t)→\{ name\cdot t \cdot name \}) |
  Filter(fun(e)→ e\cdot sal \geq \text{minSalary}\cdot \text{getRate}("USD", cur)) | From(employee))
  \text{(2000, "USD")})
)(fun(ffrom, rto)→\ldots)
```

Next, the QIR runtime is called, and the query is normalized to:

```r
Project(fun(t)→\{ name\cdot t \cdot name \}) |
Filter(fun(e)→ e\cdot sal \geq (e \cdot \text{sal}, 20000) | From(employee))
```

then translated to SQL as:

```r
SELECT T.name AS name FROM (SELECT * FROM (SELECT * FROM employee) AS E WHERE E.sal >= 2000 ) AS T
```

This query is sent to PostgreSQL, and the results are translated back to QIR using $\text{PostgreSQL}\rightarrow\text{VAL}$, then to R using $\text{VAL}\rightarrow R$.

### 7 Implementation and Results

**Implementation.** BOLDR consists of QIR, host languages, and databases. To evaluate our approach, we implemented the full stack, with R and SimpleLanguage as host languages and PostgreSQL, HBase and Hive as databases. Table 1 gives the numbers of lines of Java code for each component to gauge the relative development effort needed to interface a host language or a database to BOLDR. All developments are done in Java using the Truffle framework.

<table>
<thead>
<tr>
<th>Component</th>
<th>L.o.c.</th>
<th>Remark</th>
</tr>
</thead>
<tbody>
<tr>
<td>FastR / SimpleLanguage</td>
<td>17500/4000</td>
<td>12500/4000</td>
</tr>
<tr>
<td>PostgreSQL / Hbase / Hive binding</td>
<td>150/100/100</td>
<td>150/100/100</td>
</tr>
</tbody>
</table>

Table 1: BOLDR components and their sizes in lines of code.

As expected, the bulk of our development lies in the QIR (its definition and normalization) which is completely shared between all languages and database backends. Compared to its 4000 L.o.c., the development cost of languages or database drivers, including translations to and from QIR is modest (between 700 and 1000 L.o.c.).

Even though our main focus is on Truffle-based languages, on which we have full control over their interpreters, all our requirements are also met by the introspection capabilities of modern dynamic languages. For instance, in R, the `environment` function returns the environment affixed to a closure as a modifiable R value, the `body` function returns the body of a closure as a manipulable abstract syntax tree, and the `formals` function returns the modifiable names of the arguments of a function. These introspection capabilities could be used to achieve an even more seamless integration.

**Experiments.** The results of our evaluation\(^1\) are reported in Table 2. Queries named TPCH-\(n\) are SQL queries taken from the TPC-H performance benchmark [TPC 2017]. These queries feature joins, nested queries, grouping, ordering, and various arithmetic subexpressions. Table 2A and 2B illustrate how our approach fare against hand-written SQL queries. Each row reports the expected cost (in disk page fetches as reported by the EXPLAIN ANALYZE commands) as well as the actual execution time on a 1GB dataset. Row SQL represents the hand-written SQL queries, Row SQL+UDFs represents the same SQL queries where some subexpressions are expressed as function calls of stored functions written in PL/SQL. Row R represents the SQL queries generated by BOLDR from equivalent R

\(^1\)The test machine was a PC with Ubuntu 16.04.2 LTS, kernel 4.4.0-83, with the latest master from the Truffle/Graal framework and PostgreSQL 9.5, Hive 2.1.1, and HBase 1.2.6 all with default parameters.
expressions, and Row R+UDFs represents the same SQL queries as in Row SQL+UDFs generated by BOLDR from equivalent R expressions with R UDFs. Lastly, for R+UDFs, we added untranslatable subexpressions kept as host language nodes to impose a call to the database embedded R runtime. The results show that we can successfully match the performances of Row SQL with Row R, and that BOLDR outperforms PostgreSQL in Row R+UDFs against Row SQL+UDFs. This last result comes from the fact that PostgreSQL is not always able to inline function calls, even for simple functions written in PL/SQL. In stark contrast, no overhead is introduced for a SQL query generated from an R program, since the normalization is able to inline function calls properly, yielding a query as efficient as a hand-written one. As an example, the TPCH-15 query was written in R+UDFs as:

```r
q = max_rev = function() max(revenue)
```

This represents the same SQL queries as in Table 2 of BOLDR’s performances. The work in the literature closest to BOLDR is T-LINQ and P-LINQ by Cheney et al. [2013] which subsumes previous work on LINQ and Links and gives a comprehensive “practical theory of language integrated queries”. In particular, it gives the strongest results to date for a language-integrated queries framework. Among their contributions stand out: (i) a quotation language (a λ-calculus with list comprehensions) used to express queries in a host language, (ii) a normalization procedure ensuring that the translation of a query cannot cause a query avalanche, (iii) a system which guarantees that well-typed queries can be normalized, (iv) a general recipe to implement language-integrated queries and (v) a practical implementation that outperforms Microsoft’s LINQ. Some parts of our work are strikingly similar: our intermediate representation is a λ-calculus using reduction as a normalization procedure. However, our work diverges radically from their approach because we target a different kind of host languages. T-LINQ requires a pure host language, with quotation and anti-quotation support and a type-system. Also, T-LINQ only supports one (type of) database per query and a limited set of operators (essentially, selection, projection, and join, expressed as comprehensions). While definitely possible, extending T-LINQ with other operators (e.g., “group by”) or other data models (e.g., graph databases) seems challenging since their normalization procedure hard-codes in several places the semantics of SQL. The host languages we target do not lend themselves as easily to formal treatment, as they are highly dynamic, untyped, and impure programming languages. We designed BOLDR to be target databases agnostic, and to be easily extendable to support new languages and databases. We also endeavored to lessen the work of driver implementers (adding support for a new language or database) through the use of embedded host language expressions, which take advantage of the capability of modern databases to execute foreign code. This contrasts with LINQ where adding new back-ends is known to be a difficult task [Eini 2011]. Lastly, we obtained formal results corresponding to those of T/P-LINQ by grafting a specific SQL type system on our framework.

QIR is not the first intermediate language of its kind. While LINQ proposes the most used intermediate query representation, recent work by Ong et al. [2014] introduced SQL+*, an intermediary query representation whose goal is to subsume SQL and NoSQL. In this work, a carefully chosen set of operators is shown to be sufficient for the client side (see our future work in the Conclusion), therefore the queries in which the two functions target the same database perform better, since they are evaluated in a unique database implying less network delays and less work on the client side.

### 8 RELATED WORK

The work in the literature closest to BOLDR is T-LINQ and P-LINQ by Cheney et al. [2013] which subsumes previous work on LINQ and Links and gives a comprehensive “practical theory of language integrated queries”. In particular, it gives the strongest results to date for a language-integrated queries framework. Among their contributions stand out: (i) a quotation language (a λ-calculus with list comprehensions) used to express queries in a host language, (ii) a normalization procedure ensuring that the translation of a query cannot cause a query avalanche, (iii) a system which guarantees that well-typed queries can be normalized, (iv) a general recipe to implement language-integrated queries and (v) a practical implementation that outperforms Microsoft’s LINQ. Some parts of our work are strikingly similar: our intermediate representation is a λ-calculus using reduction as a normalization procedure. However, our work diverges radically from their approach because we target a different kind of host languages. T-LINQ requires a pure host language, with quotation and anti-quotation support and a type-system. Also, T-LINQ only supports one (type of) database per query and a limited set of operators (essentially, selection, projection, and join, expressed as comprehensions). While definitely possible, extending T-LINQ with other operators (e.g., “group by”) or other data models (e.g., graph databases) seems challenging since their normalization procedure hard-codes in several places the semantics of SQL. The host languages we target do not lend themselves as easily to formal treatment, as they are highly dynamic, untyped, and impure programming languages. We designed BOLDR to be target databases agnostic, and to be easily extendable to support new languages and databases. We also endeavored to lessen the work of driver implementers (adding support for a new language or database) through the use of embedded host language expressions, which take advantage of the capability of modern databases to execute foreign code. This contrasts with LINQ where adding new back-ends is known to be a difficult task [Eini 2011]. Lastly, we obtained formal results corresponding to those of T/P-LINQ by grafting a specific SQL type system on our framework.

**Table 2: Evaluation of BOLDR’s performances**
to express relational queries as well as NoSQL queries (e.g., queries over JSON databases). Each operator supports configuration options to account for the subtle differences in semantics for distinct query languages and data models (treatment of the special value NULL, semantics of basic operators such as equality, . . . ). In opposite, we chose to let the database expose the operators it supports in a driver.

Grust et al. [2010] present an alternative compilation scheme for LINQ, where SQL and XML queries are compiled into an intermediate *table algebra* expression that can be efficiently executed in any modern relational database. While this algebra supports diverse querying primitives, it is designed to specifically target SQL databases, making it unfit for other back-ends.

Our current implementation of BOLDR is at an early stage and, as such, it suffers several shortcomings. Some are already addressed in existing literature. First, since we target dynamic programming languages, some forms of error cannot be detected until query evaluation. This problem has been widely studied and, besides T-LINQ works such as SML# [Ohori and Ueno 2011] or ScalaDB [García et al. 2010] use the static type system of the language to ensure the absence of a large class of runtime errors in generated queries. Second, our treatment of effects is rather crude. Local side effects, such as updating mutable references scoped inside a query, work as expected while observable effects, such as reading from a file on host machine memory, is unspecified behavior. The work of Cook and Wiedermann [2011] shows how client-side effects can be re-ordered and split apart from queries. Third, at the moment, when two sub-queries target different databases, their aggregation is done in the QIR runtime. Costa Seco et al. [2015] present a language which allows manipulation of data coming from different sources, abstracting their nature and localization. A drawback of their work is the limitation in the set of expressions that can be handled. Our use of arbitrary host expressions would allow us to circumvent this problem.

9 CONCLUSION AND FUTURE WORK

We presented BOLDR, a framework that allows programming languages to express complex queries containing application logic such as user-defined functions. These queries can target any source of data as long as it is interfaced with the framework, more precisely, with our intermediate language QIR. We provided methods for programming languages and databases to interface with QIR, as well as an implementation of the framework and interfaces for R, SimpleLanguage, PostgreSQL, HBase, and Hive. We described how QIR reduces and partially evaluates queries in order to take the most of database optimizations, and showed that BOLDR generates queries performing on a par with handwritten SQL queries.

Future work includes the creation of a domain-specific language to define translations from QIR to database languages, leaving the implementation details to the language itself, with the associated gains of speed, clarity, and concision. Currently, queries targeting more than one data sources are partially executed in the host language runtime. We plan to determine when such queries could be executed efficiently in one of the targeted data sources instead. For instance, in a join between two distinct data sources, it could be more efficient to send data from one data source to the other that will complete the join. ORMs and LINQ can type queries since they know the type of the data source. BOLDR cannot do it yet since QIR queries may contain dynamic code, and we do not want to type-check the whole host language. While we cannot foresee any general solution, we believe that to exploit any type information available we could use *gradual typing* [Siek and Taha 2006], a recent technique blending static and dynamic typing in the same language. In particular, we would be able to use type information from database schemas (when available) to infer types for the queries.

### A QIR AS A DATABASE LANGUAGE

An important design decision of any intermediate query representation is the set of supported database operators. The choice might prove to be difficult due to the following conflicting aspects:

- an operator may be specific to a particular data model (e.g., computing the transitive closure in a graph database);
• an operator may be generic enough but not natively supported by some back-ends (NoSQL databases usually do not support join operations).

The set of operators exposed by the intermediate representation should be broad enough so that the end users do not have to re-implement operators in host languages, and generic enough so that translating queries from the intermediate representation to a database representation stays manageable.

To experiment with this vast design space, we equip the QIR with a particular database language, dubbed MEM. MEM shares its values and expressions with QIR, and its data operators constitute a first attempt at defining a core set of operators that should be implemented by BOLDR even though some back-ends may not support them natively.

**Definition A.1 (MEM database language).** The MEM language MEM = (E\_\text{MEM}, V\_\text{MEM}, O\_\text{MEM}, \text{MEM}) is defined by:

- E\_\text{MEM} = E\_\text{QIR}
- O\_\text{MEM} = \{\text{Filter}, \text{Project}, \text{Join}\}
- V\_\text{MEM} is the set of finite terms generated by the grammar

\[
V ::= \text{fun}^n(x) \rightarrow q \mid \text{if } f \text{ then } h \rightarrow (\text{filter } t) \text{ else } (\text{filter } t) \mid [ ] \mid l
\]

\[
\text{MEM} = (\text{Filter}, \text{Project}, \text{Join})
\]

Of course the semantics of the MEM target language would be incomplete without the definition of a driver for MEM:

**Definition A.2 (MEM driver).** The driver for the MEM database language is the 3-tuple (\text{EXP}\_\text{MEM}(\_), \text{VAL}\_\text{MEM}(\_), \text{MEM}\_\text{MEM}(\_)) of total functions such that:

- \text{VAL}\_\text{MEM}(\_): V\_\text{QIR} \rightarrow V\_\text{MEM} \cup \{\Omega\} is the identity function.
- \text{MEM}\_\text{MEM}(\_): V\_\text{QIR} \rightarrow V\_\text{QIR} \cup \{\Omega\} is the identity function.
- \text{EXP}\_\text{MEM}(\_): E\_\text{QIR} \rightarrow E\_\text{MEM} is defined by case as

\[
\text{EXP}\_\text{MEM}(\text{Filter}(f \mid l)) = \text{fun}^n(l) \rightarrow l
\]

\[
\text{EXP}\_\text{MEM}(\text{Project}(f \mid l)) = \text{fun}^n(l) \rightarrow l
\]

\[
\text{EXP}\_\text{MEM}(\text{Join}(f_1, f_2 \mid l_1, l_2)) = \text{fun}^n(l) \rightarrow \text{Project}(f_1 \mid l_1) \land \text{Project}(f_2 \mid l_2)
\]

The definition of the operators supported by MEM is straightforward and well-known to functional programmers. Filter(f \mid l) is implemented as a recursive function that iterates through an input list l and keeps elements for which the input predicate f returns true. Project(f \mid l) (also known as map) applies the function f to every element of l and returns the list of the outputs of f. Lastly, the Join(f_1, f_2 \mid l_1, l_2) operator is defined as a double iteration which tests for each record element h_1 of l_1 and each record element h_2 of l_2 if the pair h_1, h_2 satisfies the join condition given by the function f_2, then the two records are concatenated and added to the result.

Finally, the function f_1 is applied to every element to obtain the final result. For simplicity, we express Join in terms of Project and Filter, but we could have given a direct definition.

B QIR TO SQL

In this section, we give technical details of our translation from QIR to SQL. The set of supported operators of the translation is:

\[
\text{O}_\text{SQL} = \{\text{Project}, \text{From}, \text{Filter}, \text{GroupBy}, \text{Sort}, \text{Join}, \text{Limit}\}
\]

The semantics of Filter, Project, and Join was described in Section A. From(n) loads the contents of a table from its name, GroupBy(f, agg \mid l) partitions elements of l for which f returns the same value into groups, and returns the list of the results of applying agg to each group. Sort(f \mid l) sorts a collection l using a sorting key returned by applying f to each element of the list. The specific translation \text{EXP}_\text{SQL} is defined by the judgment q \rightarrow sql\_e stating that a QIR expression q can be translated into a SQL expression e. The derivation of this judgment is given by the rules in Figure 5.

Data operators are translated into their SQL equivalent. Consts are translated using the translation function \text{VAL}_\text{SQL} provided by the driver; identifiers are translated as they are. Field access is handled by (SQL-field-simp) if the first argument is syntactically an identifier, and by (SQL-field-cplx) otherwise. Basic operators are translated into their SQL counterpart by rule (SQL-basic-op). Conditional expressions are translated into the corresponding CASE construct. Host language expressions are evaluated using a BOLDR-provided function that calls the evaluator of the host language in the database. Lastly, the (SQL-error) rule propagates errors and ensures that the whole translation fails if one of the sub-cases fails.

Next we show that the type-system defined in Section 4.2 statically checks QIR terms that can be soundly translated into SQL, that is, QIR terms in which all subterms can be handled by our specific translation. This property is formally stated by Theorem 4.2:

Let \( q \in E\_\text{QIR} \) such that \( \Gamma \vdash q : T, q \rightarrow^* v, \) and v is in normal form. If \( T \equiv B \lor T \equiv R \lor T \equiv R \text{ list} \) then \( v \rightarrow sql\_e \), SQL

To prove this theorem, we proceed in three steps. First, we show through the usual property of subject reduction that the normal form v has the same type T as q. Second, we show that normal forms of a given type have a particular shape. Lastly, we show by case analysis on the translation rules that the translation can never fail.

**SUBJECT-REDUCTION.** Let \( q \in E\_\text{QIR} \) and \( \Gamma \) an environment from QIR variables to QIR types. If \( \Gamma \vdash q : T, q \rightarrow q' \), then \( \Gamma \vdash q' : T \).

We prove the property by induction on the typing derivation.

- \( (\text{fun}^l(x) \rightarrow q_1) q_2 \rightarrow q_1 \mid (\text{fun}^l(x) \rightarrow q_1, x/q_2) : \)

\[\Gamma, f : T' \rightarrow T, x : T' \vdash q_1 : T \quad \Gamma \vdash q_2 : T' \]

\[\Gamma \vdash (\text{fun}^l(x) \rightarrow q_1) q_2 : T\]

- if true then \( q_1 \) else \( q_2 \) \rightarrow \( q_1 \):

\[\Gamma \vdash \text{true} : \text{bool} \quad \Gamma \vdash q_1 : T \quad \Gamma \vdash q_2 : T \]

\[\Gamma \vdash \text{if true then } q_1 \text{ else } q_2 : T\]
Figure 5: Translation from QIR to SQL
The next step is to show that a normal form of QIR has a particular shape depending on its type.

**Definition B.1.** A normal form \( v \) of QIR is a finite production of the following grammar:

\[
\begin{align*}
v & ::= x \\
       & | \text{fun}^x(x) \rightarrow v \\
       & | v \quad \text{first } v \not= \text{fun}^x(x) \rightarrow v \\
       & | c \\
       & | \text{op}(v_1, \ldots, v_n) \\
       & | \text{if } v \text{ then } v \text{ else } v \\
       & | v_1 \text{ } ; \quad \text{first } v \not= \text{true and first } v \not= \text{false} \\
       & | [ ] \\
       & | v_1 := v \\
       & | v \rightarrow v \\
       & | v \not\equiv [ ] \text{ and first } v \not\equiv v_1 := v \\
       & | o(v_1, \ldots, v_1, \ldots, v) \\
\end{align*}
\]

We now isolate a subset of normal forms that are translatable into SQL, that is a set of normal forms for which the translation succeeds.

**Definition B.2 (Translatable normal forms).** We define translatable normal forms as the finite terms produced by the following grammar:

\[
\begin{align*}
s & ::= r ::= | r ::= s | s @ s | \text{Project} \left( \text{fun}^x(x) \rightarrow r \mid s \right) \\
       & | \text{From} \left( b \right) | \text{Filter} \left( \text{fun}^x(x) \rightarrow b \mid s \right) \\
       & | \text{Join} \left( \text{fun}^x(x) \rightarrow r, \text{fun}^x(x) \rightarrow b \mid s \right) \\
       & | \text{GroupBy} \left( \text{fun}^x(x) \rightarrow s, \text{fun}^x(x) \rightarrow r \mid s \right) \\
       & | \text{Sort} \left( \text{fun}^x(x) \rightarrow r \mid s \right) \\
\end{align*}
\]

**Lemma B.3.** Let \( v \) be a normal form of QIR and \( \Gamma \) an environment from QIR variables to QIR types such that \( \forall x \in \text{dom}(\Gamma), \Gamma(x) \equiv R \), and \( \Gamma \vdash v : T \), then:

- If \( T \equiv R \rightarrow R \rightarrow R \) then \( v \equiv \text{fun}^x(x) \rightarrow \text{fun}^x(x) \rightarrow R \)
- If \( T \equiv R \rightarrow R \rightarrow R \) then \( v \equiv \text{fun}^x(x) \rightarrow b \)
- If \( T \equiv R \rightarrow R \rightarrow R \) then \( v \equiv \text{fun}^x(x) \rightarrow r \)
- If \( T \equiv \{ l : T, \ldots, l : T \} \) then \( v \equiv x or v \equiv \{ l : v, \ldots, l : v \} \)

**Proof.**

**Hypothesis 1 (H1).** \( v \) is in normal form

**Hypothesis 2 (H2).** \( \forall x \in \text{dom}(\Gamma), \Gamma(x) \equiv R \)

We prove the property by structural induction on the typing derivation of \( \Gamma \vdash v : T \). We proceed by case analysis on \( T \):

- If \( T \equiv B \) then if the last typing rule used in the proof of \( \Gamma \vdash v : B \) is the coercion rule, then \( \Gamma \vdash v : \{ l : B \} \) list, so by induction hypothesis \( v \equiv s \) else
  - If \( v \equiv x \) then impossible since \( \Gamma \vdash x : \Gamma(x) \equiv R \) by Hypothesis H2
  - If \( v \equiv \text{fun}^x(x) \rightarrow v' \) then impossible since \( \Gamma \vdash \text{fun}^x(x) \rightarrow v' : T_1 \rightarrow T_2 \)
  - If \( v \equiv v_1 \downarrow v_2 \) then by the typing rule of the application: \( \Gamma \vdash v_1 : T_1 \rightarrow T_2 \), so by induction hypothesis \( v_1 \equiv \text{fun}^x(x) \rightarrow v \), which is impossible by Hypothesis H1
  - If \( v \equiv c \) then \( v \equiv b \)
  - If \( v \equiv \text{op}(v_1, \ldots, v_n) \) then by the typing rule of operators: \( \forall i \in 1..n, \Gamma \vdash v_i : B_i \), so by induction hypothesis \( \forall i \in 1..n, v_i \equiv b, \text{so } v \equiv \text{op}(v_1, \ldots, v_n) \equiv \text{op}(b, \ldots, b) \equiv b \)
  - If \( v \equiv \text{if } v_1 \text{ then } v_2 \text{ else } v_3 \) then by the typing rule of the conditional expression: \( \forall i \in 1..3, \Gamma \vdash v_i : B_i \), so by induction hypothesis \( \forall i \in 1..3, v_i \equiv b, \text{so } v \equiv \text{if } v_1 \text{ then } v_2 \text{ else } v_3 \equiv \text{if } b \text{ then } b \equiv b \)
  - If \( v \equiv \{ l_1 : v_1, \ldots, l_n : v_n \} \) then impossible since \( \Gamma \vdash \{ l_1 : v_1, \ldots, l_n : v_n \} : \{ l_1 : T_1, \ldots, l_n : T_n \} \)
  - If \( v \equiv [ ] \) then impossible since \( [ ] \) cannot be typed
  - If \( v \equiv v_1 \downarrow v_2 \) then impossible since \( \Gamma \vdash v_1 \downarrow v_2 : R \) list
  - If \( v \equiv v_1 @ v_2 \) then impossible since \( \Gamma \vdash v_1 @ v_2 : R \) list
  - If \( v \equiv v' \cdot l \) then by the typing rule of the record destructor: \( \Gamma \vdash v' : \{ l_1 : T_1, \ldots, l_n : T_n \} \), so by induction hypothesis either \( v' \equiv \{ l_1 : v, \ldots, l_n : v \} \), which is impossible by Hypothesis H1, or \( v' \equiv x \), then \( v \equiv v' \cdot l \equiv b \)
  - If \( v \equiv \text{Project}(v_1 \uparrow v_2) \) then impossible since \( \Gamma \vdash \text{Project}(v_1 \uparrow v_2) : R \) list
  - If \( v \equiv \text{From}(v') \) then impossible since \( \Gamma \vdash \text{From}(v') : R \) list
  - If \( v \equiv \text{Filter}(v_1 \uparrow v_2) \) then impossible since \( \Gamma \vdash \text{Filter}(v_1 \uparrow v_2) : R \) list
  - If \( v \equiv \text{Join}(v_1, v_2 \uparrow v_3, v_4) \) then impossible since \( \Gamma \vdash \text{Join}(v_1, v_2 \uparrow v_3, v_4) : R \) list
  - If \( v \equiv \text{GroupBy}(v_1, v_2 \uparrow v_3) \) then impossible since \( \Gamma \vdash \text{GroupBy}(v_1, v_2 \uparrow v_3) : R \) list
  - If \( v \equiv \text{Sort}(v_1 \uparrow v_2) \) then impossible since \( \Gamma \vdash \text{Sort}(v_1 \uparrow v_2) : R \) list

- If \( T \equiv R \) then
  - If \( v \equiv x \) then \( v \equiv b \)
  - If \( v \equiv \text{fun}^x(x) \rightarrow v' \) then impossible since \( \Gamma \vdash \text{fun}^x(x) \rightarrow v' : T_1 \rightarrow T_2 \)
  - If \( v \equiv v_1 \downarrow v_2 \) then impossible for the same argument as for \( T \equiv B \)
  - If \( v \equiv c \) then impossible since \( \Gamma \vdash c : \text{typeof}(c) \equiv B \)
If \( \vdash e : T \) then by the typing rule of \( \text{Type} \) or \( \text{Pair} \) or \( \text{Proj} \) so by induction hypothesis \( e \vdash T \).

If \( \vdash e : \top \) then by the typing rule of \( \text{Abs} \) or \( \equiv \) or \( \text{Implies} \).

If \( \vdash \langle e \rangle : \Gamma \) then by the typing rule of \( \text{Record} \) or \( \text{App} \) or \( \text{Cons} \) so by induction hypothesis \( e \vdash \Gamma \).

If \( \vdash e : \Gamma \) then by the typing rule of \( \text{Fun} \) or \( \exists \) or \( \text{Let} \) or \( \text{Case} \) or \( \text{Var} \) so by induction hypothesis \( e \vdash \Gamma \).

If \( \vdash e : \text{filter} \Gamma \) then by the typing rule of \( \text{Filter} \) or \( \text{List} \) so by induction hypothesis \( e \vdash \Gamma \).
- If \( v = \text{fun}^f(x) \rightarrow v' \) then by typing rule of the function:
  \( \Gamma, x : R \vdash v' : R \), so by induction hypothesis \( v' \equiv r \), so
  \( v = \text{fun}^f(x) \rightarrow v' \equiv \text{fun}^f(x) \rightarrow r \)
- all other cases are impossible for the same arguments as for
  \( T \equiv R \rightarrow B \)
- If \( T \equiv R \rightarrow R \cdot \) then
- If \( v = \text{fun}^f(x) \rightarrow v' \) then by typing rule of the function:
  \( \Gamma, x : R \vdash v' : R \cdot \) list, so by induction hypothesis \( v' \equiv s \), so
  \( v = \text{fun}^f(x) \rightarrow v' \equiv \text{fun}^f(x) \rightarrow s \)
- all other cases are impossible for the same arguments as for
  \( T \equiv R \rightarrow B \)
- If \( T \equiv R \cdot \) list \( \rightarrow R \) then
- If \( v = \text{fun}^f(x) \rightarrow v' \) then by typing rule of the function:
  \( \Gamma, x : R \cdot \) list \( \vdash v' : R \cdot \) list, so by induction hypothesis \( v' \equiv r \), so
  \( v = \text{fun}^f(x) \rightarrow v' \equiv \text{fun}^f(x) \rightarrow r \)
- all other cases are impossible for the same arguments as for
  \( T \equiv R \rightarrow B \)
- If \( T \equiv R \rightarrow R \rightarrow B \) then
- If \( v = \text{fun}^f(x) \rightarrow v' \) then by typing rule of the function:
  \( \Gamma, x : R \rightarrow v' : R \rightarrow B \), so by induction hypothesis \( v' \equiv \text{fun}^f(x) \rightarrow B \), so
  \( v = \text{fun}^f(x) \rightarrow v' \equiv \text{fun}^f(x) \rightarrow \text{fun}^f(x) \rightarrow B \)
- all other cases are impossible for the same arguments as for
  \( T \equiv R \rightarrow B \)
- If \( T \equiv T_1 \rightarrow B \) then
- If \( v = \text{fun}^f(x) \rightarrow v' \) then by typing rule of the function:
  \( \Gamma, x : B \vdash v' : B \), so by induction hypothesis \( v' \equiv \text{fun}^f(x) \rightarrow B \), so
  \( v = \text{fun}^f(x) \rightarrow v' \equiv \text{fun}^f(x) \rightarrow B \)
- all other cases are impossible for the same arguments as for
  \( T \equiv R \rightarrow B \)
- If \( T \equiv \{ t_1, \ldots, t_n \} \) then
  - If \( v = x \) then the property is true
- If \( v = \text{fun}^f(x) \rightarrow v' \) then impossible since
  \( \Gamma \vdash \text{fun}^f(x) \rightarrow v' : T_1 \rightarrow T_2 \)
  - If \( v = v_1 \) then impossible for the same argument as for
    \( T \equiv B \)
  - If \( v = c \) then impossible since \( \Gamma \vdash c : \text{typeof}(c) \equiv B \)
  - If \( v = \text{op}(v_1, \ldots, v_n) \) then impossible since
    \( \Gamma \vdash \text{op}(v_1, \ldots, v_n) : B \)
  - If \( v = \text{if } v_1 \text{ then } v_2 \text{ else } v_3 \) then impossible since
    \( \Gamma \vdash \text{if } v_1 \text{ then } v_2 \text{ else } v_3 : B \)
  - If \( v = \text{if } v_1 \text{ then } v_2 \) then impossible since
    \( \Gamma \vdash \text{if } v_1 \text{ then } v_2 : B \)
  - If \( v = (l : v_1, \ldots, l : v_n) \) then the property is true
  - If \( v = \text{Project}(v_1 | v_2) \) then impossible since
    \( \Gamma \vdash \text{Project}(v_1 | v_2) : R \cdot \) list
  - If \( v = \text{From}(v') \) then impossible since
    \( \Gamma \vdash \text{From}(v') : R \cdot \) list
  - If \( v = \text{Filter}(v_1 | v_2) \) then impossible since
    \( \Gamma \vdash \text{Filter}(v_1 | v_2) : R \cdot \) list

We have shown that well-typedness of a QIR term restricts its syntactic form. We can finally show that terms that have a relational type can be translated into SQL by our specific translation.

**Lemma B.4.** Let \( v \) be a normal form of QIR such that \( v \equiv b \), or \( v \equiv r \), or \( v \equiv s \), then \( \exists \in \text{SQL} \) such that \( v \rightarrow e \).

**Proof.** The rules of Figure 5 used to derive the judgment \( \rightarrow e \) are syntax-directed (at most one rule applies), and terminate since the premises are always applied on a strict syntactic subterm of the conclusion. Thus, since \( v \) is finite by definition of a QIR term, the translation derivation is finite and unique. We can therefore prove our lemma by induction on the translation derivation. We will use \( \text{II} \) (Hypothesis Induction) to denote the induction hypothesis and proceed by case analysis.

- If \( v \equiv b \) then
  - If \( v = c \) then:
    \[
    \begin{align*}
    \text{(SQL-const)} & \quad c \rightarrow e \\
    \text{(SQL-i)} & \quad (\text{HI}) \quad e_i \neq \Omega \quad i \in 1..3
    \end{align*}
    \]
  - If b1 then b2 else b3 then:
    \[
    \begin{align*}
    \text{(SQL-if)} & \quad (\text{HI}) \quad e_i \neq \Omega \quad i \in 1..3
    \end{align*}
    \]
- If \( v \equiv r \) then
  - If \( v = x \) then:
    \[
    \begin{align*}
    \text{(SQL-tdestr-simpl)} & \quad \text{SELECT CASE WHEN } (e_1) \text{ THEN } (e_2) \text{ ELSE } (e_3) \text{ END} \\
    \text{(SQL-var)} & \quad (\text{HI}) \quad x \rightarrow \chi \\
    \text{x} \cdot l & \quad (\text{SQL-SELECT}) \quad \text{SELECT } X \cdot L
    \end{align*}
    \]
  - If \( v = \text{op}(b_1, \ldots, b_n) \) then:
    \[
    \begin{align*}
    \text{(SQL-basic-op)} & \quad (\text{HI}) \quad e_i \neq \Omega \quad i \in 1..n \\
    \text{a(b_1, \ldots, b_n)} & \quad (\text{SQL-SELECT}) \quad \text{SELECT } (e_1, \ldots, (e_n))
    \end{align*}
    \]
  - If \( v \equiv r \) then
    - If \( v = x \) then:
      \[
      \begin{align*}
      \text{(SQL-var)} & \quad (\text{HI}) \quad x \rightarrow \chi
      \end{align*}
      \]
- If $v = \{ h_1:b_1, \ldots, h_n:b_n \}$ then:

$$
\begin{align*}
&\text{(SQL-record)} \\
&\frac{}{\text{SELECT}\ (e_i) \text{ AS } X_i, \ldots, (e_n) \text{ AS } X_n}
\end{align*}
$$

- If $v \equiv s$ then:
  - If $v = \text{r} :: \{ \}$ then:

$$
\begin{align*}
&\text{(SQL-icons-empty)} \\
&\frac{e_i \neq \Omega}{\text{TMP fresh}}
\end{align*}
$$

- If $v = \text{r} :: s$ then:

$$
\begin{align*}
&\text{(SQL-join)} \\
&\frac{\text{SELECT } * \text{ FROM } (e_1) \text{ AS } X_1, \ldots, (e_n) \text{ AS } X_n}{\text{r} :: \{ \}}
\end{align*}
$$

- If $q = \text{GroupBy}(\text{fun}^f(x) \rightarrow \text{r} \mid s)$ then:

$$
\begin{align*}
&\text{(SQL-group-by)} \\
&\frac{e_i \neq \Omega \quad i \in 1..n}{\text{GROUP BY } (e_2) \text{ AS } X}
\end{align*}
$$

- If $q = \text{Sort}(\text{fun}^f(x) \rightarrow \text{r} \mid s)$ then:

$$
\begin{align*}
&\text{(SQL-sort)} \\
&\frac{e_i \neq \Omega \quad i \in 1..2}{\text{ORDER BY } (e_1)}
\end{align*}
$$

Last, but not least, we can prove our sound translation theorem as a direct corollary of Theorem 4.1, and Lemmas B.3 and B.4.

**Translation.** Let $q \in \text{EqR}$ such that $\emptyset \vdash q :T, q \rightarrow^* v$, and $v$ is in normal form. If $T \equiv B$ or $T \equiv R$ or $T \equiv \text{ list}$ then $v \rightarrow s$, SQL.

By Theorem 4.1, we have: $\emptyset \vdash v :T$. Thus, we can apply Lemma B.3 and deduce: $v \equiv b$ or $v \equiv \text{r}$ or $v \equiv s$. Consequently, by Lemma B.4, we obtain: $v \rightarrow s$, SQL. Finally, we apply the rule (db-op) of our generic translation, and since the specific translation was able to translate $v$ to SQL, it is able to translate the sources of the query (which are syntactically strict subterms of $v$) to SQL. Therefore, the rule (db-op) succeeds at translating $v$ to a term of SQL.

**C FROM R TO QIR**

We give some technical details of our translation from R to QIR. Even though we do not modify the parsing of R programs, we still need to translate R closures into QIR λ-expressions. For instance, given the R program:

```r
less2000 = function(x)( x <= 2000 )
t = tableRef("employee", "PostgreSQL")
subset(t, less2000(sal))
```

we want to end up with the QIR term (before normalization):

$$
\begin{align*}
&\text{fun}(\text{less2000}) \rightarrow \\
&\text{Filter}(\text{fun}(r) \rightarrow \text{less2000} \cdot \text{sal} \mid t)
\end{align*}
$$

which becomes, after normalization:

$$
\begin{align*}
&\text{Filter}(\text{fun}(r) \rightarrow \leq (x, 2000), \text{From(employee)})
\end{align*}
$$

While it seems obvious from this example that the function `less2000` should be translated into `fun(x) \rightarrow \leq (x, 2000)`, it is not always sound to do so. Indeed, a variable $x$ can be soundly translated into a QIR variable if it is not the subject of side effects, otherwise accesses to $x$ must be nested inside host language expressions $\overline{R}(\sigma, x)$ so that the correct value for $x$ can be retrieved.

The set of modified variables can be approximated by the $\text{Mod}$ function defined as such:
We define the judgment \( \gamma, \sigma \vdash e \rightsquigarrow q \), which means that given a set of modified variables \( \gamma \) and an R environment \( \sigma \), the R expression \( e \) can be translated into a QIR expression \( q \). The derivation of this judgment is given by the rules in Figure 6. We define the translation \( \overline{\exp}_R(\sigma, e) = q \) as \( \gamma, \sigma \vdash e \rightsquigarrow q \).

Constants and identifiers are translated into QIR equivalents. Anonymous functions are translated into QIR lambdas. More interesting is the translation of the built-in function \text{subset}. Its first two arguments are recursively translated, but the second one requires some post-processing. Recall that in the case of \text{subset}, the second argument \( e_2 \) contains free variables bound to column names. We simulate this behavior by introducing a lambda abstraction whose argument is a fresh name \( t \) and replace all occurrences of a free variable \( x \) in the translation by \( t \cdot x \). The last argument is expected to be a list of column names we use to build a lambda abstraction to project over these names. The \text{merge} function is similarly translated into a \text{Join} operator. The last interesting case is when a local variable is defined in a sequence of expressions. If the variable is not modified in the subsequent expression, then we translate this definition into a lambda application. Expressions that are not handled are kept in host expression nodes that will be evaluated either locally, in a QIR term that is not shipped to a database, or remotely, using the R runtime embedded in a database.

Now that we have defined the translation of expressions in a given scope, we can easily define the translation of values from R to QIR. The translation of constants, sequences and data frames is straightforward. The translation of a closure function \( \text{function}(x_1, \ldots, x_n)_{\sigma}[e] \) is simply the translation of the body wrapped in a lambda: \( \text{fun}(x_1, \ldots, x_n) \rightarrow \overline{\exp}_R(\sigma, e) \).
